to the 4th power

Consider a platform target subjected to a normal impact of explosive products generated by detonating a bare charge in space. It is suggested that the loading impulse may be approximated by the total momentum of that portion of the fluid which impacts at the target. Assuming impulsive dynamic response, and assuming that the ensuing damage is proportional to the kinetic energy imparted to the structure by the blast, we get a particularly simple law:  $\text{Damage} \sim W^2/R^4$  ( $W$  is charge mass,  $R$  is range). This model is an idealization of a solar panel (or antenna) extended in a paddle-like fashion from a relatively rigid and massive core structure. It is also shown that this law implies that no advantage can be realized by re-arranging the mass of a single bare charge in a cluster configuration of smaller sub-charges, which would be dispersed and detonated via an idealized isotropic scheme.

Keywords: gas dynamics, exhaust plumes, Sprengstoff.

## ACKNOWLEDGEMENTS

This work is part of a study involving gas dynamics of exhaust plumes from spacecrafts. It was conducted under the cognizance of Distinguished Professor Allen E. Fuhs, who suggested extending our understanding of gasdynamics in space to the treatment of blast effects on spacecrafts. I wish to thank Professor Fuhs for his creative guidance and deeply appreciate his continuous support. The GRP code used for the blast computation is a product of mutual research conducted by Professor M. Ben-Artzi and myself. The fruitful collaboration of Professor Ben-Artzi is gratefully acknowledged.

Distribution Statement A is correct for this report. The material in this report is taken from open literature.

## 1. INTRODUCTION

The advent of space-based weapon systems in our times has raised the prospects of future "Star Wars" conflicts, rendering the potential use of explosive devices against space targets a present day engineering reality. The warhead of choice in space seems to be of the fragmentation type, for obvious reasons. The effectiveness of fragments is unhampered by the space environment (lack of air may even be helpful). By contrast, bare charges in space are considerably less efficient than in air. One may wonder why this is so since in air, as in space, the same amount of chemical energy is released through the detonation process. The explanation is that the difference is in the much larger mass involved in the air blast, relative to the bare charge mass.

For a more comprehensive explanation, we take a close look at the process by which an explosive-driven air blast wave is generated. The explosive products effectively constitute a rapidly expanding spherical piston (typical initial speed around 6 km/sec), which drives an intense shock wave into the surrounding air. At a typical range of  $100R_0$  (and with air density equal to about 1/1000 of charge density), the mass of air entrained by the shock is about 1000 times the charge mass. Thus, the highly concentrated initial explosive energy, has spread over a much larger mass than that of the charge, via the mechanism of wave propagation in compressible media, resulting in an increased momentum. For a comprehensive treatment of blast waves in air the reader is referred to Baker[1].

It is also worthwhile noting that explosive products in space typically attain hypersonic speed prior to impacting at the target. The flow velocity in an air blast is typically subsonic or somewhat supersonic. It is thus expected that the actual gasdynamic interaction between the blast flow and a stationary target, will be fundamentally different in these two cases.

We contend that blast effects in space may still be of practical interest for reasons such as the following :

- (i) Notwithstanding the poor efficiency of a bare charge, its use should not be ruled out altogether. Fragments would contribute to existing - and potentially hazardous - population of space debris, underlining the obvious fact that there is no absolutely safe standoff distance from an isotropic fragmentation warhead. A clean bare charge may thus be a reasonable alternative.
- (ii) Even a fragmentation warhead has some residual blast capacity, which has to be considered either as a factor in enhancing target damage, or as a threat to be reckoned with in determining a safe standoff distance.

The key idea of the present model is a combination of the assumption that target dynamic response is related primarily to total blast impulse, and the physically plausible notion that this impulse is equal to the total momentum of that portion of the expanding explosive products which impacts at the target. The sense in which this simple notion constitutes an approximation to a proper gasdynamic analysis of the interaction between the fluid and the target, is clarified in Ch. 2. In that chapter we also present an illuminating comparison between impulsive blast loading in air and in space.

In order to demonstrate the ChargeMass-Range-Damage relationship implied by our impact blast approximation, we chose a simple target model: A cantilever beam with a rigid-perfectly plastic stress-strain relationship. It represents an extended structural element such as a solar panel or an antenna. We make use of studies conducted by Mentel [2] and by Bodner and Symonds [3], which showed that by and large, the effect of accelerating the beam impulsively was to cause a rotation about a plastic hinge at the point of support. The final angle of rotation is generally proportional to the initial kinetic energy, so that equating damage with that angle, results in damage being proportional to the square of the impulse imparted to the target by the blast loading. A presentation of this dynamic response model, including a sample case, is given in Ch. 3.

Our ChargeMass-Range-Damage relationship may imply some far-reaching conclusions when applied to the analysis of a more general configuration than the single-charge/single-target case. In Ch. 4 we present a simple analysis of a sub-munition configuration of  $N$  bare charges, concluding that it seems to have no advantage in efficiency, relative to a single charge of equal mass. Sections 5 and 6 contain conclusions and references, correspondingly.

We conclude the introduction by listing the main assumptions made in the present study :

- (a) Blast loading and target response are uncoupled. This is true since typically the target mass is much larger than the mass of that portion of the explosive products which impacts on it.
- (b) Dynamic target response is independent of specific loading time history. It depends solely on total (time-integrated) impulse.
- (c) The target is a panel extended as a relatively supple cantilever. It is supported by a relatively rigid and massive core structure.
- (d) The charge is a sphere detonated at its center. The expansion is spherically symmetric.
- (e) Target surface is normal to local flow vector.
- (f) Target orbital velocity relative to the center of the charge is negligible, compared with the velocity of the expanding products.

## 2. IMPACT BLAST LOADING

Consider the expanding explosive products impacting at a target as shown in Fig. 2-1. By regarding the fluid as an ensemble of non-interacting particles moving at velocity  $U(R,t)$ , and by assuming a no-rebound normal impact at the surface, the pressure time history is given by :

$$P_s(t) = \rho(R,t)[U(R,t)]^2 \quad (2-1)$$

How is this simple impact mechanism related to the actual gasdynamic interaction between the expanding explosive products and the target? When a target is located at a range of at least several charge radii, two features in the free stream of the oncoming fluid are significant : The flow is highly hypersonic (Mach number 20 or higher), and the static pressure is very small, which means that  $P + \rho U^2 \approx \rho U^2$ . These facts were born out by a numerical computation which we performed for a typical high explosive characterized by the following parameters :

$$\rho_0 = 1800 \text{ (kg m}^{-3}\text{)}$$

$$\gamma_{CJ} = 3$$

$$D_{CJ} = 8 \text{ (m ms}^{-1}\text{)}$$

$$Q_0 = D_{CJ}^2 / [2(\gamma_{CJ}^2 - 1)] = 4 \text{ (MJ kg}^{-1}\text{)}$$

(2-2)

Where  $Q_0$  was determined by assuming that the detonation corresponded to the CJ point on the explosive Hugoniot curve, and that the detonation products were an ideal gas with a specific-heat ratio  $\gamma_{CJ}$ . The spherically expanding flow was computed by integrating the Euler equations for isentropic flow via a high-resolution conservative finite-difference scheme [4-6]. The initial conditions were the self-similar flow field of a just-detonated spherical charge given by Taylor [7]. The code GRP with which the computation was performed is described and listed in Appendix A.

Consider the flow at a stationary target, which begins at the moment of arrival of the expanding explosive products (Fig. 2-2). A qualitative description of the ensuing flow pattern is made by observing its evolution in time. Immediately following the initial (normal) impact, the fluid is stopped at the target by a backward-propagating shock wave reflected from the surface. Since the target is of

finite extent, the fluid between the shock and the surface is accelerated laterally, and streamlines that tend to curve around the target are being formed. If the oncoming flow were stationary, the flow field would evolve toward the familiar configuration of a detached bow-shock positioned at a relatively narrow standoff distance from the surface.

Let us find the post-shock pressure in these two limiting phases. In the initial phase, the fluid is stopped at the target by a reflected shock (Fig. 2-3a), and in the pseudo-stationary phase (Fig. 2-3b), the shock is stationary. In either case we find the post-shock pressure to be given by a pressure-recovery expression of the form :

$$P_2 = \alpha \rho U^2 \quad (2-3)$$

Where  $\alpha$  is a constant related to the appropriate  $\gamma$  (assuming the expanded explosive products are an ideal gas). The governing equations in the reflected shock case are :

$$\rho(U+S) = \rho_2 S$$

$$\rho(U+S)^2 = P_2 \quad (2-4)$$

$$\rho(\gamma+1)/(\gamma-1) = \rho_2 \quad (\text{strong shock})$$

Where the unknowns are  $\rho_2$ ,  $P_2$ ,  $S$ .

The equations for the stationary shock case are :

$$\rho U = \rho_2 U_2$$

$$\rho U^2 = P_2 + \rho_2 U_2^2 \quad (2-5)$$

$$\rho(\gamma+1)/(\gamma-1) = \rho_2 \quad (\text{strong shock})$$

Where the unknowns are  $\rho_2$ ,  $U_2$ ,  $P_2$ . Thus, solving for  $\alpha$  in the two cases represented by equations (2-4) and (2-5), we get :

$$\text{Reflected shock} \quad \alpha = [(\gamma + 1)/2]^2 \quad (2-6)$$

$$\text{Stationary shock} \quad \alpha = 2/(\gamma + 1)$$

In either case, since the gas is not dense, the effective range of  $\gamma$  is somewhere between 1.0 and 1.4, so that setting  $\alpha = 1$  is an approximation commensurate with the overall crudeness of the present impact blast model. Since the flow in the layer between the shock and the target is low subsonic (at least it is so away from target edges), the post-shock pressure is a reasonable substitute for the surface pressure. Also,  $\alpha = 1$  is an appropriate approximation where the flow is so rarefied that it is collisionless. In this limit,  $\alpha = 1$  corresponds to full thermal accommodation of re-emitted molecules from a presumably cold surface.

The foregoing analysis constitutes a justification of the impact approximation to the surface pressure (2-1). Now we turn to the task of evaluating the impulse which is defined as the time-integrated surface pressure. Using the impact approximation (2-1), the impulse is given by :

$$I(R) = \int_0^{\infty} P_s(t) dt = \int_0^{\infty} \rho(R,t) [U(R,t)]^2 dt \quad (2-7)$$

Let us introduce a Lagrange mass coordinate  $m$  which enables a transformation from the Euler system  $(R,t)$  to the Lagrange system  $(m,t)$ . The differential relation associated with this transformation at constant  $R$  is :

$$dm = 4\pi R^2 \rho(R,t) U(R,t) dt \quad (2-8)$$

Since it is assumed that the fluid is not accelerated at any  $(R,t)$  in the range of interest for blast loading, the velocity  $U(R,t)$  can be regarded as function *solely of the mass coordinate*, so that  $U(R,t) = U(m)$ . Using (2-8) we are then able to cast the impact blast expression (2-7) in the following simple and physically appealing form :

$$I(R) = Z/4\pi R^2$$

$$Z = \int_0^W U(m) dm \quad (2-9)$$

The upper limit  $W$  in (2-9), which is consistent with the upper limit  $\infty$  in (2-7), implies that the total impulse is somewhat overestimated, since it contains contributions from the innermost layers of the explosive products that will arrive at the target as  $t \rightarrow \infty$ .

The total momentum  $Z$  is thus a constant which can be evaluated for any specific explosive charge by numerical integration. We performed this computation with the code GRP described in Appendix A. In doing so for the typical explosive (2-2), we found out that the impulse (2-9) was a reasonable approximation at ranges as low as  $R = 3R_0$ . Furthermore, it was found that  $Z$  could be approximated by the maximum attainable momentum for the given charge mass and energy  $W(2Q_0)^{1/2}$ , to within about 6%. Apparently, the total momentum is not overly sensitive to the exact velocity distribution function  $U(m)$ , so that assuming a value of  $Z$  appropriate to the uniform distribution  $U(m) = (2Q_0)^{1/2}$  is a reasonable approximation. Thus we finally arrive at the following closed-form approximation for the blast impulse:

$$I(R) = \kappa W(2Q_0)^{1/2} / 4\pi R^2 \quad (2-10)$$

$\kappa = 1$

Where the coefficient  $\kappa$  is retained in order to suggest that its value be determined more accurately from detailed experimental or computational data, in the event that such data become available. At present our best estimate is  $\kappa = 1$ .

There is one comparison, however, which can readily be made with available data. We refer to impulsive blast loading in air, such as given by Baker (Ref. 1, Fig. 6.3 in the supplement). The comparison is conveniently made with a non-dimensional form of (2-10), which is rewritten as:

$$\bar{I} = I(R) [4\pi R_0^2 / W(2Q_0)^{1/2}] = (R/R_0)^{-2} \quad (2-11)$$

The air blast data has to be converted to the same normalization scheme as in Eq. (2-11), before the comparison can be made. Considering the definition of  $\bar{I}$  in (2-11) above, and the definition of scaled range and air blast impulse (Table 6.2 of Ref. 1), this conversion is done by multiplying the scaled air impulse and range by the following coefficients (sea-level air is assumed):

Impulse Multiplier	$\beta = 3(2\gamma)^{-1/2}(4\pi/3)^{1/3} (P_a/\rho_a Q_0)^{1/6} (\rho_a/\rho_0)^{1/2} = .01204$	
Range Multiplier	$\delta = (4\pi/3)^{1/3} (\rho_0 Q_0/P_a)^{1/3} = 67.06$	(2-12)
$\rho_a = 1.3 \text{ (kg m}^{-3}\text{)}$	$P_a = 0.1 \text{ (MPa)}$	$\gamma = 1.4$

The air blast conversion was done by a small code which is given in Appendix B. The air and space blast impulses are shown in Fig. 2-4. We note that at ranges larger than about 10 charge radii, the air blast impulse is higher than the space impulse, and the gap widens as the range increases. This observation is consistent with the qualitative explanation given in the introduction, which attributed this effect to the increase in the entrained air mass at higher range. At ranges lower than 10 charge radii, the air mass is relatively insignificant, so that one may expect the blast impulses in air and in space to be comparable. Indeed, the inverse-square variation of impulse with range is apparent for the air blast at low range. In absolute values, however, the low-range space impulse is higher by a factor of about 1.7. This might be interpreted as indicating that choosing  $\kappa = 1/1.7$  would be the appropriate "calibration". However, we do not propose to do so, since we are not able to trace the various factors affecting the low-range impulse as given by Baker [1]; they may somehow depend on the presence of air, as well as on other parameters such as target size and equation of state of the explosion products.

### 3. TARGET DYNAMIC RESPONSE

For the sake of constructing representative Charge-Mass-Range-Damage relations from our impact approximation to the blast impulse (2-10), we suggest a simple idealized structure as target model. It is a cantilever beam made of a metal characterized by a rigid-perfectly plastic stress-strain relation.

This model is supposed to represent an extended spacecraft component such as a solar panel or an antenna. The core structure is assumed to be much more massive and rigid than the extended structural element, so that the cantilever can be idealized as being rigidly supported. The sole dynamic and structural parameters are hence those of the cantilever.

For this purpose we make use of an experimental and theoretical investigation of uniform cantilever beams subjected to impulsive loading that was conducted by Mentel [2]. Aluminum alloy beams were held in a massive support that was gliding along a rail at speed  $V$ , until it was abruptly stopped by a very massive anvil. After the system came to rest, the beams were observed to have rotated through an angle  $\theta$  about the point of support, with little deformation elsewhere (Fig. 3-1).

The theoretical model suggested by Mentel [2] for predicting  $\theta(V)$ , can be described as comprising two stages. Immediately following the impact, the beam commences rotating rigidly about the support point, with an angular momentum equal to the pre-collision moment of momentum about that point. This application of the principle of conservation of moment of momentum entails an abrupt re-distribution of velocity in the beam, with velocity being proportional to distance from support, and the tip moving at  $1.5 V$ . The angle  $\theta$  is subsequently determined from the requirement that the rotational kinetic energy be dissipated as plastic hinge work  $M_p \theta$ . The resulting  $\theta(V)$  expression is :

$$\theta = (3/8)\mu LV^2/M_p \quad (3-1)$$

We now make one more step in formulating the model, in that we postulate that *the angle  $\theta$  is a measure of damage*. Using the following expressions for  $M_p$ ,  $\mu$  and  $V$  :

$$M_p = (1/4)Yl^2$$

$$\mu = \rho_p h \quad (3-2)$$

$$V = I(R)/\mu$$

We get from (2-10) and (3-1) the following ChargeMass-Range-Damage (W-R- $\theta$ ) relationship :

$$\begin{aligned} R &= CW^{1/2} \\ C &= [(3/16\pi^2\theta) (LQ_0/\rho_p Yh^3)]^{1/4} \end{aligned} \tag{3-3}$$

We note that the effective range for a specified target and "damage level"  $\theta$  , is proportional to the square root of the charge mass  $W$  .

Using the data for the typical explosive (2-2), and the following data for a specific aluminum beam, we get for this sample case :

$$\begin{aligned} h &= 0.002 \text{ (m)} \\ L &= 1.0 \text{ (m)} \\ \rho_p &= 2700 \text{ (kg m}^{-3}\text{)} \\ Y &= 300 \text{ (MPa)} \\ C &= 1.85 \theta^{-1/4} \text{ (m kg}^{-1/2}\text{)} \end{aligned} \tag{3-4}$$

The ChargeMass-Range-Damage relationship corresponding to this sample case is depicted in Fig. 3-2.

Figure 3-1. Cantilever Beam with Plastic Hinge

Figure 3-2. Charge Mass - Range - Damage Curves for Cantilever Beam

#### 4. CLUSTER CONFIGURATION

In a cluster configuration, the gain in damage is presumably a result of a favorable design tradeoff between reduced charge mass and reduced range. Can such a gain be achieved for a space system, assuming the ChargeMass-Range-Damage law (3-3) to hold? It can be shown that by adopting some simple strategy of sub-munition dispersion and initiation, equation (3-3) implies no gain in target damage.

Let us assume for the sake of a reasonably simple analysis, that dispersion and initiation of sub-charges would take place according to the following scheme :

- (a) The  $N$  sub-charges appear to fan out from a common virtual center, moving at equal speeds. At subsequent times, their centers are uniformly distributed over an expanding spherical envelop.
- (b) The target moves at a constant velocity relative to the virtual center. Its point of closest approach to that center is at range  $R$ .
- (c) The timing for dispersion is chosen so that the target intersects (tangentially) with the spherical envelop at the point of closest approach (Fig. 4-1). This is also the point at which the blast from a single-charge configuration detonated at the virtual center, would have impacted at the target.
- (d) All sub-munitions are detonated at this "moment of closest approach".
- (e) It is assumed that each spherical cap of area  $4\pi R^2/N$  will contain one, and only one, sub-charge. The probability of the charge location on that cap is assumed to be uniformly distributed. The expected location on the cap is hence that latitude line  $\phi$  which divides the cap into two parts of equal area (Fig. 4-2).
- (f) It is assumed that the target is subjected to the blast of a single sub-charge, which is located on the mid-area latitude  $\phi$  of the spherical cap that surrounds the target (Fig. 4-2).

Since the area of the spherical cap subtended by  $\phi$  is  $4\pi R^2/(2N)$ , the angle  $\phi$  is given by :

$$\sin(\phi/2) = (2N)^{-1/2} \quad (4-1)$$

We seek a comparison between the deflection  $\theta$  for a single charge  $(W, R)$ , and the deflection  $\theta_N$  in the sub-munition case ( $W_N = W/N$ ,  $R_N = 2R\sin(\phi/2)$ ). From the ChargeMass-Range-Damage law (3-3), using also Eq. (4-1), we get :

$$(\theta_N/\theta) = (W_N/W)^2 (R/R_N)^4 = 1/4$$

(4-2)

Consequently, there is no potential gain in a tradeoff between charge mass and range, for a cluster configuration with the aforementioned dispersion scheme. The factor  $1/4$ , along with the mass overhead inherent in constructing a multi-charge configuration, indicate that in causing blast damage, a single charge is more effective than an equal-mass isotropically dispersed cluster.

Figure 4-1. Target Intercept at Closest Approach

Figure 4-2. Spherical Cap Surrounding the Target

## 5. DISCUSSION AND CONCLUSIONS

Our analysis pertains to a bare explosive charge initiated at a point of closest approach to the target. We have shown that the loading impulse on a planform target is given by the impact approximation (2-7), which states that the impulse is proportional to the charge mass and inversely proportional to the range squared. The impulse in space has been compared with impulse in air at sea-level. It was found that the two are quite comparable at close range (10 charge radii or less), exhibiting identical variation with range. At far ranges, the impulse in air is the higher one. This is consistent with the notion that spreading the explosive energy over larger air mass results in larger momentum (and hence reflected impulse). We then proceeded to develop the Charge-Mass-Range-Damage law (3-3) for an impulse-responsive target, which states that blast damage is proportional to the square of the charge mass and inversely proportional to the fourth power of the range. These results were obtained by introducing extensive simplifications in the analysis of gasdynamic interaction, and in the analysis of dynamic target response. We have further shown that this damage law also implies that no gain can be achieved by an idealized cluster configuration of bare sub-charges, relative to a single charge of equal total mass.

It is worthwhile noting that all assumptions introduced in the course of formulating the impact blast approximation and the structural dynamic response to impulsive loading, imply that target damage is overestimated. The only exception is the approximation in setting  $\alpha = 1$ , which can be readily rectified by assigning to  $\alpha$  the reflected shock value given in (2-6). Furthermore, we assumed that the pressure at the midpoint of the target, is the pressure everywhere on the target. Due to flow around the edges, the average pressure is lower than the midpoint pressure. Also, targets are not everywhere normal to the flow (and charge/target attitude is not a design parameter). Oblique impact obviously entails reduced target loading. In the area of structural dynamic response, a time-distributed loading function generally delivers less kinetic energy to the structure than an impulsive loading of equal total impulse, resulting in reduced deformation (damage). Thus, while the present model may be regarded as an over estimate when applied to a sure-fail analysis, it is particularly suitable in determining a sure-safe range.

## APPENDIX A. The GRP Code

The purpose of this Appendix is to provide a concise description of the GRP code, and a listing of its CHARGE version. It is intended for users that have had prior experience in implementing schemes for solving the Euler equation of compressible flow. The theoretical background of GRP schemes constitutes the principles on which the code is founded. Some familiarity (at least) with this background, as given in References 4, 5 and 6 is indispensable to any implementation of GRP schemes. Reference 4 is recommended as an introduction. The planar GRP scheme is fully described in Reference 5, and the duct-flow GRP scheme on which the present CHARGE version is based is given in Reference 6. (In CHARGE version the flow is spherical and the "duct" area is set to  $X(I)**2$ , but the code can handle any area variation - see subroutines CROSS and RATIO below).

In GRP schemes, second-order accuracy is achieved by considering a piecewise linear interpolation of the flow in each cell (Fig. A-1), from which second-order accurate fluxes at each cell interface are evaluated through an analysis of a local Generalized Riemann Problem (GRP). Briefly stated, the GRP goes one step further than the Riemann Problem (RP), in that it seeks (analytically) the first time-derivative of the flow that evolves as the "diaphragm" is removed from the cell interface, at the origin of the centered (X,T) wave paths of the RP solution. The major computational subroutines are CYCEUL where the integration of conservation laws is performed, RIEMAN where the local Riemann Problems are solved by Newton-Raphson iterations, MAGA where the closed-form expressions derived from the GRP analysis [6] are used to compute flow time-derivatives along the contact surface, FLUXE where all the previously computed information is used to extrapolate the fluxes to mid-time-step ( $T + DT/2$ ) which constitutes a second-order accurate flux.

The plan of this Appendix is as follows. Array variables, including those which carry conserved variables (mass, momentum and energy), are described in section A.1. This is followed by descriptions of general parameters (A.2), labeled COMMON variables (A.3) and all subroutines (A.4). We conclude by giving the CHARGE version listing (A.5), which should be consulted whenever a reading of this code description is attempted.

NOTE : The present CHARGE version was implemented in a GRP code version that had been converted to treat detonation waves as chemically reactive compressible flow. However, the detonation scheme is effectively neutralized by setting QDET=0 (in NETUNM). All variables pertaining to detonation, such as arrays Z(I), DZ(I), FIMZ(I), ZMDOT(I) and labeled COMMON variables containing Z in their names, should be ignored.

## A.1 Array Variables

The code GRP is organized so that all major subroutines are called with standard list of array variables which represent the integration scheme (i.e. the conservation laws), local Riemann Problem solutions and second-order accurate fluxes. Virtually all array variables are initially defined in BEGIN (initial conditions), and are subsequently updated at each time step in CYCEUL. The following list explains the meaning of these variables. Some terms used in the list are defined below.

X(I)	grid point coordinate.
U(I)	velocity in cell I.
P(I)	pressure in cell I (computed from equation of state).
RO(I)	density in cell I. This variable is time-integrated according to the law of conservation of mass. (Computed in CYCEUL).
E(I)	total energy per unit volume (including kinetic energy) in cell I. This variable is time-integrated according to the law of conservation of (total) energy. (Computed in CYCEUL).
DU(I)	velocity difference in cell I.
DP(I)	pressure difference in cell I.
DRO(I)	density difference in cell I.
DG(I)	Lagrange sound velocity difference in cell I.
DXSI(I)	the Lagrange coordinate increment defined as $RO(I)*(X(I+1)-X(I))$ , for cell I.
MIN(I)	inactive in present version.
US(I)	velocity at the contact surface obtained after the resolution of the local discontinuity at X(I) (Riemann Problem solution). It is denoted as $U^*$ in References 4-6.
PS(I)	pressure at the contact surface obtained after the resolution of the local discontinuity at X(I) (Riemann Problem solution). It is denoted as $P^*$ in References 4-6.
UIDOT(I)	time derivative of US(I) along the contact surface. (This derivative is the result of the GRP analysis. It is computed in MAGA. See Ref. 5 and 6).
PIDOT(I)	time derivative of PS(I) along the contact surface. (This derivative is the result of the GRP analysis. It is computed in MAGA. See Ref. 5 and 6).
FIMZ(I)	inactive in present version.
ZMDOT(I)	inactive in present version.

TENA(I)	momentum per unit volume $\rho(I)*U(I)$ in cell I. This variable is time-integrated according to the law of conservation of momentum. (Computed in CYCEUL).
FIRO(I)	mass flux at point X(I) (second-order accurate).
FIM(I)	momentum flux at point X(I) (second-order accurate).
FIE(I)	energy flux at point X(I) (second-order accurate).
GIP(I)	the pressure term in the momentum flux. It corresponds to $G(U)$ in References 4 and 6.
VOL(I)	volume of cell I.
Z(I)	inactive in present version.
DZ(I)	inactive in present version.

**Glossary of terms used in the array variables list :**

**Cell I** - the cell between grid points X(I) and X(I+1). All cell variables are averages per that interval.

**Difference in cell I** - the difference between values of variable at cell boundaries X(I+1) and X(I). Those values are obtained from "monotonized" piecewise linear distribution of each variable in each cell. (Fig. A-1).

**Second-order accurate flux** - the flux time-derivative at point X(I) is computed from the time-derivatives of pressure and velocity along contact surface PIDOT(I) and UIDOT(I) (in FLUXE). Then the the flux is extrapolated to the centered time point  $(T+DT/2)$ , using those derivatives. This centered value is the second-order flux for integrating the conservation laws between T and T+DT.

## A.2 Major Parameters

A list of major parameters indicating their meaning and the routine in which they are defined, is given below. Those parameters defined in NETUNM are the run input. There is no reading of an input file in this version of GRP code (and the only output is the printed output).

L	number of grid points + 1 (main program)
LL	L - 1 (MAIN PROGRAM)
T	time (MAIN0)
DT	time step (MAIN0)
TMAX	maximum time (when T.GE.TMAX the run is terminated) (NETUNM)
TMUD	time for which next printing will take place (NETUNM)
DTMUD	printing time step (NETUNM)
NCYC	serial number of time step (integration cycles) (MAIN0)
COLELA	switch to evaluate cell differences by Colella's method when COLELA.NE.0 (NETUNM)
KEYMON	key for monotonization scheme (just one is presently provided when COLELA.EQ.0) (NETUNM)
NCYCPR	frequency of line printing at each cycle (time step) (NETUNM)
STAB	CFL stability coefficient. Must be smaller than 1. (NETUNM)
DTBA	next time step computed from stability criterion (CYCEUL)
DTKOD	former time step (MAIN0)
KDT	index of cell where DTBA was determined (CYCEUL)

### A.3 Labeled COMMON variables

Labeled COMMONs are used primarily to transmit data to and from routines that perform the major computational steps of the GRP scheme, i.e, RIEMAN, MAGA and FLUXE; these routines are called from CYCEUL. When the value of any of those variables is needed for later use, whether for updating conservation variables (RO, TENA, E), or for printing, it is stored in the appropriate array. All labeled COMMON variables are grouped under labels that indicate their role, and their names are also mnemonic. Generally, suffix L means Left and suffix R means Right. It may indicate sides either with respect to a cell interface X(I), or with respect to the contact surface which separates the Right- and Left- propagating waves in a solution to the local Riemann Problem. We indicate by INPUT variables that are computed prior to calling the subroutine, and by OUTPUT variables whose value was computed within the subroutine and constitutes the result of calling that subroutine.

**COMMON /STEP0/** Parameters related to the local Riemann Problem. This is the first step in the GRP scheme.

UL, PL, ROL, CL, GL, SL - velocity, pressure, density, sound speed, Lagrange sound speed and entropy, attributed to Left side of cell interface at point X(I). (INPUT)

USTAR, PSTAR - velocity and pressure at the contact surface obtained when the local discontinuity is resolved (i.e., the solution to the local Riemann Problem). The omission of L or R suffix indicates that P and U are continuous across the contact surface. (OUTPUT)

RSTARL, CSTARL, GSTARL - density, sound speed and Lagrange sound speed on the Left side of the contact surface. (OUTPUT)

WL - Lagrange velocity of propagation of the Left-moving shock, relative to the fluid. (OUTPUT)

UW(6) - velocity of propagation of each wave front (Fig. A-3), relative to the inertial system (X). (OUTPUT)

HELEML - logical variable. If HELEMLEQ.TRUE. the Left-propagating wave is a shock. Otherwise it is a (centered) rarefaction wave. (OUTPUT)

NFLUX - integer variable. It denotes the region in the Riemann solution wave structure, which contains the point X(I) for all time. Refer to Fig. A-3 for illustration. (OUTPUT)

LAMDAL, RATEL, TEMPL, TEMPSL, ZL, ZSTARL - inactive.

**COMMON /STEP1/** Parameters related to the time-derivative evaluation of the GRP scheme, performed in MAGA. The time-derivatives of P and U along the contact surface are the main result of MAGA.

**DUIDT, DPIDT** - time-derivatives of velocity and pressure along contact surface. (OUTPUT)

**ASTARL** - The directional derivative of U along the fan characteristic at the trailing characteristic of the Left rarefaction wave. It is not evaluated when the Left wave is a shock. (See References 4-6) (OUTPUT)

**DGIDTL, DRIDTL** - time-derivatives of Lagrange sound speed and density along the left side of the contact surface. (OUTPUT)

**DSDAL** - Lagrange spatial derivative of entropy on the left side of contact surface, prior to removal of the partition at  $X(I)$ .

**SH, RAT** - the cross-section area and the x-derivative of  $\ln(SH)$ . They are user-defined in CROSS and RATIO respectively.

**DSDASL** - entropy derivative used in the special "sonic" case (i.e, when  $NFLUX=2$  or  $NFLUX=5$ ). See References 5,6 for details. (OUTPUT)

**LAMDSL, DZDAL, BETACL, DZDASL** - inactive.

**COMMON /GRADS/** Used to transmit flow gradients (that exist in fluid prior to removal of the partition at  $X(I)$ ) to MAGA.

**DUDXIL, DPDXIL, DGDXIL, DRDXIL, DSDXIL** - gradients of U, P, G, RO, S (with respect to Lagrange coordinate). They are computed in CYCEUL for transmission to MAGA. (INPUT)

**DZDXIL** - inactive.

**COMMON /FI/** Used to return values of updated flux and cell-interface variables from FLUXE.

**FIH1, FIH2, FIH3** - second-order flux of mass, momentum flow (just  $RO*U^{**2}$ ) and energy. They are extrapolated to Half the time step  $T + DT/2$ . (OUTPUT)

**GIH** - the value of P at  $T + DT/2$

UXN, PXN, GXN, ROXN - values of U, P, G, RO extrapolated to New time  $T+DT$ , at cell-interface. They are used in CYCEUL to get tentative (pre-monotonized) new cell differences. (OUTPUT)

ZXN, FIH4, ZMDOTL, ZMDOTR - inactive.

## **A.4 Description of Subroutines**

### **MAIN PROGRAM**

The task of this program is to allocate array space for the NMAT arrays required by the present version of GRP code. The length of each array is L. The allocation is done by calling MAIN0. This standard calling sequence is maintained hereafter, thus facilitating modifications.

### **MAIN0**

This subroutine functions as an overall organization routine. It can be read as a kind of flow-chart of the entire computation. First, run set-up is done by calling once to NETUNM (data) and BEGIN (initial conditions). Then a loop over time steps is begun. In each cycle the integration by one time step is performed by calling CYCEUL, and subsequently boundary conditions are implemented by calling SAFAE. Whenever T.EQ.TMUD, results are printed by calling PRINT and TMUD is updated by adding DTMUD.

### **NETUNM**

Here data are set for a particular run. User is invited to modify this routine. There is no input file. This routine is called just once from MAIN0. Note that the detonation data section is skipped when QDET.EQ.0.

### **BEGIN**

Initial conditions are set-up in this routine. The configuration of some nominal case is given in present version. (In CHARGE version it is the detonated spherical charge, using the Taylor self similar solution as initial conditions). User is called to modify this routine so as to generate any other desired initial configuration.

### **TAYLOR**

The purpose of this routine, along with ancillary routines INIDAT, RUNGE and DERIV, is to compute the self-similar Taylor solution [7] of a detonated spherical charge, and implement it as initial conditions for the GRP computation of the ensuing expansion. TAYLOR is called once by BEGIN.

The core of the solution is the numerical (Runge-Kutta) integration of two coupled ordinary differential equations. The integration variable is  $\Psi$ . (The flow velocity normalized by  $DCJ$  is given

by  $U = \exp(-\psi)$ ). The two dependent variables are  $X$  - the normalized radial coordinate ( $X = 1$  at the sphere boundary), and  $C$  - the normalized speed of sound. The integration is carried out by calling RUNGE, which in turn calls DERIV for the evaluation of derivatives. Data for the TAYLOR computation is set up by calling (just once) INIDAT.

The initial conditions needed in BEGIN are values of mass, momentum and (total) energy per cell. These are most accurately computed by spatially integrating the Taylor solution, resulting in lumped mass, momentum and energy per cell, which are then divided by the cell volume. This refinement is significant since gradients are high near the charge boundary ( $X = 1$ ). A total mass and energy check for the entire sphere is performed and printed.

#### INIDAT, RUNGE, DERIV

Subroutines used only in conjunction with the Taylor initial conditions setup. See TAYLOR above.

#### RATIO, CROSS

User-defined routines. If  $A(X)$  is the duct cross-section area, then  $CROSS(X) = A(X)$  and  $RATIO(X) = D[\ln(A(X))]/DX$ .

#### CYCEUL

This is the central computation routine. All major stages of the GRP scheme are performed by calling specific subroutines from CYCEUL. Then  $RO(I)$ ,  $TENA(I)$  and  $E(I)$  are updated to new time  $T + DT$  by solving the appropriate conservation laws in CYCEUL.

The first loop (DO 1) performs a set of preparatory steps as follows :

- (a) CALL RIEMAN - Solving the local Riemann Problem at each  $X(I)$ .
- (b) CALL MAGA - Solving the local Generalized Riemann Problem at each  $X(I)$ .
- (c) CALL FLUXE - Computing second-order fluxes at  $X(I)$ .
- (d) Evaluation of cell-interface finite differences  $DU(I)$ ,  $DP(I)$ ,  $DRO(I)$  in each cell. These will be used at the future time step (after monotonicization) for piecewise-linear interpolation of the flow in each cell. (See definition of  $DUDXIL$ ,  $DPDXIL$ , ..., just preceding the call to MAGA in this loop).

Note that in present CHARGE version additional computation of PRESS, PULSE1, ..., PULSE4 has been added. It is just informative and does not interfere in any way with the execution of the

GRP scheme. The purpose of this computation is to monitor the numerical solution and to observe the accuracy within which the asymptotic value of the momentum integral  $Z$  (Eq. 2-9 above) is approached.

In the second loop (DO 2), the integration of the three conservation laws is performed, using second-order fluxes that had been computed in loop 1. Flow variables such as  $P(I)$  and  $U(I)$  are computed in this loop from the conserved variables. The cycle computation is concluded by calling BDOK1 for monotonization of  $DU(I)$ ,  $DP(I)$  and  $DRO(I)$ .

#### SAFAE

In this routine user-defined boundary conditions are implemented. Present version (CHARGE) contains rigid wall at the center of the sphere  $X(2)=0$ , and an "open boundary" at the outer computational zone limit  $X(L)$ . The rigid wall condition is achieved by setting up a virtual antisymmetric cell next to the boundary cell, so that the solution to the local Riemann Problem will result in a non-moving contact surface ( $USTAR=0$ ). The open boundary is an approximation to an ideally non-reflecting boundary. Here the virtual cell is  $I=L$ , and the flow in it is defined as a "continuation" of the flow in the adjacent last cell  $I=LL$ .

#### BDOK1

Here the tentative cell-interface differences  $DV(I)$  are monotoned according to neighboring average cell values  $V(I-1)$ ,  $V(I)$  and  $V(I+1)$ . The basic idea is that the cell-interface slope  $DV(I)$  should have the same sign as the average slope  $V(I+1)-V(I-1)$ . When  $V(I)$  is a local extremum  $DV(I)$  is set to zero. Also, the absolute value of  $DV(I)$  is constrained so that the jump from a cell-interface value to the adjacent average value  $V(I)$ , will never be of opposite sign to  $DV(I)$ .

#### DCOLE

When COLELA option is used (not in present CHARGE version), the pre-monotonized slopes are simply the centered difference  $(V(I+1)-V(I-1))/2$ . Note that even under this option, the monotoneization routine BDOK1 is subsequently called.

#### PRINT

Printing of results. Reading this routine is self-explanatory. Note some features added for present CHARGE version. User is called to modify this routine to his specific needs.

## **SOF**

Run termination when an error has been detected. ISTOP is an informative index. All printing of relevant information should be done at the calling routine prior to calling SOF. Note that the run is ended in SOF by deliberately causing a system error of computing SQRT(-1). This is done in order to trigger printing of the sequence of calling routines by the operating system.

## **RIEMAN**

Here a single Riemann Problem (RP) is solved by calling RIEMAN from CYCEUL. Referring to Fig. A-2, the RP is solved by finding the point of intersection (USTAR,PSTAR) of Left-propagating and Right-propagating shock/rarefaction adiabats in the (U,P) plane. Prior to the actual computation, the qualitative wave structure is determined. It is characterized by the index NCASE as follows :

NCASE = 1 - Left wave is rarefaction, Right wave is shock.

NCASE = 2 - Both waves are shock.

NCASE = 3 - Left wave is shock, Right wave is rarefaction.

NCASE = 4 - Both waves are rarefaction.

The computation of (USTAR,PSTAR) is coded separately for each case. Newton-Raphson iteration is employed, the first guess being the intersection of the Left and Right rarefaction branches (or their extrapolations), which is done in closed-form. Since in a smooth flow this guess is close to the exact (USTAR,PSTAR), little extra CPU effort is spent on subsequent Newton-Raphson iterations. These are truly needed only in regions of shock wave computation.

The computation in RIEMAN is concluded by computing UW(1),...,UW(5) (UW(6)=infinity). From these wave speeds, the flux index NFLUX that denotes the location of the X-axis on the (X,T) wave diagram of the RP solution (Fig. A-3), is evaluated. It is later needed in subroutine FLUXE.

## MAGA

The major purpose of this routine is to compute DUIDT and DPIDT along the contact surface of the RP solution. Since U and P are continuous across the contact, so are their time-derivatives along the contact. Thus, DUIDT and DPIDT are solved from a set of two linear equations. The coefficients of each equation are determined by GRP analysis of the wave on one side. See References 4-6 (particularly Ref. 6) for details.

## FLUXE

The major task of this routine is to compute second-order fluxes. This is done in two phases. The first phase is up to statement 9 CONTINUE, where using NFLUX the X-suffixed values of flow variables and their time-derivatives are defined. An X-suffix means that the variable or its time-derivative are related to the line  $X = X(I)$  on the (X,T) wave diagram (Fig. A-3). In the second phase, these variables and their time-derivatives are used to extend fluxes at  $X(I)$  to Half-time-step (hence the suffix H), i.e.  $T + DT/2$ . It is these fluxes which are the second-order accurate fluxes for the integration of the conservation laws from T to  $T + DT$ . Also, cell-interface flow variables (suffix N) are extended to New time level  $T + DT$ . These are later used in defining cell differences DU(I), DP(I) and DRO(I) in CYCEUL.
